## 1 Mandatory Questions

### 1.1 Bellman Optimality Equations

The finite horizon optimality equations may be expressed as

$$v_{n+1}(s) = \sup_{a \in A_s} (r(s, a) + \sum_{j \in S} \lambda p(j|s, a) v_n(j))$$

For an optimal policy (in the limit):

$$v(s) = \sup_{a \in A_s} (r(s, a) + \sum_{j \in S} \lambda p(j|s, a) v(j))$$

The above system of equations is called Bellman Equations.

In order to write the Bellman optimality equations in vectorized form, we define non-linear operator  $\mathcal{L}$  and linear operator  $L$  on  $V$  as

$$\begin{aligned}\mathcal{L}v &= \sup_{d \in D^{MD}} \{r_d + \lambda P_d v\} \\ Lv &= \max_{d \in D^{MD}} \{r_d + \lambda P_d v\}\end{aligned}$$

where the notation used is defined as below:

$d$ : policies

$D^{MD}$ : policies which are Markovian and Deterministic

$v$ : vector of value function (each entry in column vector for a particular state)

$\lambda$ : discount factor

$r_d$ : reward function (each entry in column vector for a particular state)

$P_d$ : transition probability matrix The solution to Bellman optimality equations can be expressed as:

$$v = \mathcal{L}v$$

To show that  $\mathcal{L}$  is a contraction mapping

Assumption: The set of states  $S$  is discrete,  $\mathcal{L}$  maps  $V \rightarrow V$ . An operator  $T : U \rightarrow U$  is a contraction mapping if  $\exists \lambda, 0 \leq \lambda < 1$  such that

$$\|Tv - Tu\| \leq \lambda \|v - u\|$$

$\forall u$  and  $v$  in  $U$ .

Let  $u, v \in V$ , fix  $s \in S$ , let  $Lv(s) \geq Lu(s)$  and let

$$a_s^* = \operatorname{argmax}_{a \in A_s} \left\{ r(s, a) + \sum_{j \in S} \lambda p(j|s, a) v(j) \right\}$$

$$\begin{aligned}
0 &\leq Lv(s) - Lu(s) \\
&\leq r(s, a_s^*) + \sum_{j \in S} \lambda p(j|s, a_s^*) v(j) \\
&\quad - r(s, a_s^*) - \sum_{j \in S} \lambda p(j|s, a_s^*) u(j) \\
&= \lambda \sum_{j \in S} p(j|s, a_s^*) [v(j) - u(j)] \\
&\leq \lambda \sum_{j \in S} p(j|s, a_s^*) \|v - u\|_\infty \\
&= \lambda \|v - u\|_\infty
\end{aligned}$$

$$\implies Lv(s) - Lu(s) \leq \lambda \|v - u\|_\infty$$

Repeating this argument in the case that  $Lu(s) \geq Lv(s)$

$$\begin{aligned}
Lu(s) - Lv(s) &\leq \lambda \|v - u\|_\infty \\
\implies |Lv(s) - Lu(s)| &\leq \lambda \|v - u\|_\infty
\end{aligned}$$

Taking sup. on both sides,

$$\begin{aligned}
\sup_s \{|Lv(s) - Lu(s)|\} &\leq \sup_s \lambda \|v - u\|_\infty \\
\|\mathcal{L}v - \mathcal{L}u\|_\infty &\leq \lambda \|v - u\|_\infty \\
\implies \mathcal{L} &\text{ is a contraction mapping}
\end{aligned}$$

$$\begin{aligned}
0 &\leq \|\mathcal{L}v^* - v^*\|_\infty \\
&\leq \|\mathcal{L}v^* - v^n\|_\infty + \|v^n - v^*\|_\infty \\
&= \|\mathcal{L}v^* - \mathcal{L}v^{n-1}\|_\infty + \|v^n - v^*\|_\infty \\
&\leq \lambda \|v^* - v^{n-1}\|_\infty + \|v^n - v^*\|_\infty
\end{aligned}$$

$\lim_{n \rightarrow \infty} \|v^n - v^*\| = 0$ , both quantities on RHS can be made arbitrarily small by choosing  $n$  large enough.

$$\implies \mathcal{L}v^* = v^*$$

Thus, the sequence of  $v^n$  obtained by applying the operator  $\mathcal{L}$  converges, and there exists a solution to the Bellman optimality equations

## 1.2 Policy Iteration

Policy Iteration algorithm has two steps

1. Policy Evaluation
2. Policy Improvement

Let us denote our policy at time  $n$  as  $\mu_n$  and the state value as  $v_n$ .

In **Policy Evaluation** step, we have

$$v_n(s) = \sum_a \pi(a|s) \sum_{s', r} p(s', r|s, a) (r + \gamma v_n(s'))$$

We can rewrite this equation in the matrix form as

$$v_n = r_{\mu_n} + \gamma P_{\mu_n} v_n \tag{1}$$

where  $r_{\mu_n}$  and  $P_{\mu_n}$  are terms that depend on the current policy  $\mu_n$ .

$r_{\mu_n}$  corresponds to the immediate rewards and  $P_{\mu_n}$  corresponds to the transition matrix.

In **Policy Improvement** step, we have a new policy  $\mu_{n+1}$  (policy at time  $n + 1$ ) such that

$$r_{\mu_{n+1}} + \gamma P_{\mu_{n+1}} v_n \geq r_{\mu_n} + \gamma P_{\mu_n} v_n$$

$$\Rightarrow r_{\mu_{n+1}} + \gamma P_{\mu_{n+1}} v_n \geq v_n \text{ (Using equation 1)}$$

Rearranging the terms, we get

$$r_{\mu_{n+1}} \geq (I - \gamma P_{\mu_{n+1}}) v_n \tag{2}$$

Now, when we run the policy evaluation step, we get

$$v_{n+1} = r_{\mu_{n+1}} + \gamma P_{\mu_{n+1}} v_{n+1}$$

Rearranging the terms, we get

$$(I - \gamma P_{\mu_{n+1}}) v_{n+1} = r_{\mu_{n+1}}.$$

Substituting value from (2), we get

$$(I - \gamma P_{\mu_{n+1}}) v_{n+1} \geq (I - \gamma P_{\mu_{n+1}}) v_n$$

$$\Rightarrow v_{n+1} \geq v_n$$

This implies that the state values are always either better or as good as the previous state values.

We would terminate the Policy Iteration algorithm when  $\mu_{n+1} = \mu_n$ . (Please note that in practice, we may have to check that if the difference between the two policies is less than a given threshold) Now given a finite MDP, with  $|S|$  number of states and  $|A|$  number of actions, we can not have more than  $|A|^{|S|}$  number of policies. Each policy is basically a choice of what action to take in a given state. Given the finite MDP, we can choose  $|A|$  actions in the first state, then  $|A|$  actions in the second state and so on. The total number of possible choices comes out to be  $(|A| * |A| \cdots) |S|$  times and is equal to  $|A|^{|S|}$ . In general, not all the actions may be possible in all the states so the actual number of possible policies could be less than  $|A|^{|S|}$  but it can not be more than  $|A|^{|S|}$ . This argument proves that policy iteration must terminate under a finite number of steps.

Given all the possible policies, we can group the policies into bins  $\Pi_1, \Pi_2, \dots, \Pi_N$  such that

$\forall i \in \{1, 2, \dots, N\}$ , all policies in  $\Pi_i$  are equal and

$\forall i, j \in \{1, 2, \dots, N\}$ , all policies in  $\Pi_j$  are better than all policies in  $\Pi_i$  if  $j > i$ .

Here  $N$  is the total number of bins that can be formed and is bounded by  $|A|^{|S|}$  (as we can not have more policies than the bins themselves).

This way, policy iteration guarantees that after each step, we move from one bin  $i$  to another  $j$  such that  $j > i$ . Once we reach the  $N^{th}$  bin, we terminate. Let us assume that at termination, policy iteration

has converged to  $\Pi$ . We will prove by contradiction that  $\Pi$  is the optimal policy. Let us assume that the optimal policy is not  $\Pi$  but  $\Pi^*$  such that  $\Pi^* \neq \Pi$ .

If this is the case, there is at least one state  $s$  such that

$$\begin{aligned} v_{\Pi^*}(s) &> v_{\Pi}(s) \\ \Rightarrow (I - \gamma P_{\Pi^*})v_{\Pi^*} &> (I - \gamma P_{\Pi^*})v_{\Pi} \\ \Rightarrow r_{\Pi^*} &> (I - \gamma P_{\Pi^*})v_{\Pi} \\ \Rightarrow r_{\Pi^*} + \gamma P_{\Pi^*}v_{\Pi} &> r_{\Pi} + \gamma P_{\Pi}v_{\Pi} \end{aligned}$$

This implies that the policy iteration algorithm would not have terminated at policy  $\Pi$ . This contradicts our assumption that the policy iteration algorithm terminated at a suboptimal policy. Thus the policy  $\Pi$  is indeed the optimal policy.

## 2 Track-2

The policy iteration can be written in recursive form as

$$Bv = \max_{d \in D} (r_d + (\lambda P_d - I)v)$$

where the operator  $B : V \rightarrow V$

Thus,  $Bv = Lv - v$  where  $L$  is defined as

$$Lv = \max_{d \in D^{MD}} \{r_d + \lambda P_d v\}$$

The Bellman optimality equation can be expressed as

$$Bv = 0$$

For  $u \in V$ , let  $D_v$  denote the set of policy evaluation rules. That is,  $d_v \in D_v$  if

$$d_v \in \operatorname{argmax}_{d \in D} \{r_d + (\lambda P_d - I)v\}$$

$$Bv = r_{d_v} + (\lambda P_{d_v} - I)v$$

The derivative of  $Bv$  w.r.t.  $v$  can be written as

$$\begin{aligned} \frac{d(Bv)}{dv} &= (\lambda P_{d_v} - I) \\ v^{n+1} &= r_{d_{v^n}} + \lambda P_{d_{v^n}} v^{n+1} \end{aligned}$$

Re-arranging terms, we get,

$$\begin{aligned} v^{n+1} &= (I - \lambda P_{d_{v^n}})^{-1} r_{d_{v^n}} - v^n + v^n \\ &= v^n - (\lambda P_{d_{v^n}} - I)^{-1} [r_{d_{v^n}} + (\lambda P_{d_{v^n}} - I)v^n] \\ &= v^n - \left[ \frac{d(Bv)}{dv} \right]^{-1} (Bv) \end{aligned}$$

This resembles Newton-Kantorovich iteration approach (in vector form) for finding the zero of the equation  $Bv = 0$
